1 Equivalence

One aspect of circuit design that is distinctly different than most software engineering is that when we assemble a large circuit out of a component blocks, each of the blocks can potentially influence the behavior of the others. Does this mean that every addition or change to a circuit means that we need to completely re-analyze the entire system? No, because luckily, the ways they interact are limited in a very specific way that we will discuss. It turns out they actually interact through only 2 parameters, current $I$ and voltage $V$. This leads to a new tool we will develop to help us when describing more complicated/complete circuit models; the concept of equivalence.

Equivalent circuits are used to simplify interactions between circuits. Let’s take the simplest case where interactions are only through one pair of nodes. In that case, we just have two possible quantities: the voltage across the nodes and the current flowing through the connections. The relationship between this current and this voltage would then fully define the interactions between the circuits. This is where the idea of equivalence comes in. If we have a circuit that exhibits the same $I – V$ relationship from the standpoint of a pair of nodes, the other circuit (the one you are interacting with) can’t tell the difference. The idea of equivalence is to be able to replace one (or both) of the interacting circuits with a simpler circuit that will give us the same overall behavior.

Before we move on, let’s clarify what we mean by "equivalent": **Two circuits are equivalent if they have the same $I – V$ relationship.** (An example of an $I – V$ is that of a resistor, i.e., $V = IR$ or $I = \frac{V}{R}$). This is exactly what we mean by equivalence; be careful not to overextend this definition or apply others. For example, equivalence tells us nothing about the power in a circuit and one should be careful not to assume it does.

Now why is this possibly intuitively? Since voltage and current are governed by a linear relationship for all of the circuit elements we’ve learned about, and a line can be uniquely determined by exactly two points, we can capture the original circuit with a simplified circuit that has exactly two components: a voltage (or current) source and a resistor.

**Definition 0.1 (equivalent circuit):** If we pick two terminals within a circuit, we say that another circuit is equivalent to the original circuit if it exhibits the same $I – V$ relationship at those two terminals.

Note: From the standpoint of any other nodes in the circuit (i.e. any pairs of nodes), the circuit may or may not be equivalent. Furthermore, looking at the same circuit but examining a different pair of terminals may not produce equivalent $I – V$ relationship.

At a high level, what does it take (at a minimum) to construct a line? We can either use two points along the line, or one point and the slope of the line. Remember, the equivalent circuit of a circuit will have an identical $IV$ curve, which is a line. In this class, we will construct these equivalent curves using a point and the slope. The two easiest points to collect along a line are the x-intercept (point with 0 current) and the y-intercept (point with 0 voltage).
There are two types of equivalent circuits we will construct: the **Thevenin** and the **Norton**. For the Thevenin equivalent we look at the intersection with the x-axis (zero current); for the Norton, we look at the intersection with the y-axis (zero voltage).

Next we figure out the slope of the line; remember, for an $I \times V$ curve, the slope is equal to the resistance.

We call the first circuit below, containing a voltage source and a resistor the **Thevenin equivalent circuit**; we call the second circuit, containing a current source and a resistor, the **Norton equivalent circuit**. Once we simplify the original circuit to one of the above, we can easily figure out $V_{\text{out}}$ no matter what resistor it is connected to on the right. In fact, we can convert any circuit into any one of these equivalent forms.
2 Thevenin Equivalent Circuit

Now how would you figure out $V_{Th}$ and $R_{Th}$ for the Thevenin equivalent circuit? Concretely, the procedure to solve for the Thevenin equivalent is as follows:

**Step 1, find $V_{Th}$:** Connect an open circuit across the two output terminals and measure the voltage across them. This measured $V_{OC}$ equals $V_{Th}$.

**Step 2, find $R_{Th}$:** Zero out any independent sources. Remember, this means voltage sources turn into a wire and current sources turn into an open circuit. Then apply either a test current into the terminal and measure the resultant voltage, or apply a test voltage and measure the resultant current. $R_{Th} = \frac{V_{test}}{I_{test}}$. 
3 Norton Equivalent Circuit

What about solving for the Norton equivalent circuit? First, note that $R_{No}$ is equal to $R_{Th}$, since the slope of the IV curve is the same. Now, instead of looking at the $V$ axis intercept, we find the intersection with the $I$-axis: At the intersection with the $I$-axis, the voltage drop between $A$ and $B$ is zero, which is equivalent to placing a wire between $A$ and $B$ (i.e. shorting $A$ and $B$). We denote the current through the wire be $I_{SC}$.

To put it in terms of our standard procedure:

**Step 1, find $I_{No}$**: Connect a short circuit across the two output terminals and measure the current through it. This measured $I_{SC}$ equals $I_{No}$.

**Step 2, find $R_{No}$**: Zero out any independent sources. Remember, this means voltage sources turn into a short circuit and current sources turn into an open circuit. Then apply either a test current into the terminal and measure the resultant voltage, or apply a test voltage and measure the resultant current. $R_{Th} = \frac{V_{test}}{I_{test}}$

Note that the second step doesn’t change because $R_{No}$ is equal to $R_{Th}$!

4 Equivalence Examples

Here will we find the Thevenin equivalents for a set of simple circuits.

4.1 Series Resistors

Consider the schematic:
Let’s follow the procedure given above.

**Step 1:** Note that there is already an open circuit is already connected between terminals $a$ and $b$. In this case there is no voltage or current source in the circuit. Therefore, the voltage at every node is the same, and therefore, $V_{ab,OC} = 0$. Remember, $V_{ab,OC} = V_{Th}$, so $V_{Th} = 0$.

**Step 2:** There is no source to zero out in this case. Since it will turn out to be the easier choice, we will apply a test current and measure the resulting voltage, as shown:

![Diagram of a circuit with test current and test voltage](image)

There is only one loop, and therefore all the currents in this circuit are the same.

\begin{align*}
V_{R1} &= I_{Test} R_1 \\ V_{R2} &= I_{Test} R_2 \\ V_{Test} &= V_{R1} + V_{R2} = I_{Test} R_1 + I_{Test} R_2 \\ V_{Test} &= (R_1 + R_2) I_{Test} \\ R_{Th} &= \frac{V_{Test}}{I_{Test}} = R_1 + R_2
\end{align*}

We see that equivalent resistance of these two resistors is simply their sum. We call these resistors in **series**. Note that in order to be in series, the resistors have to have the exact same current through them.

### 4.2 Parallel Resistors

Another way to arrange a circuit with two resistors and no voltage source is as follows:

![Diagram of a circuit with two parallel resistors](image)

Let’s again follow the procedure given above to find our equivalent circuit.

**Step 1:** Note that there is already an open circuit is already connected between terminals $a$ and $b$. For the same reason as the prior example, $V_{ab,OC} = 0$ in this case. Therefore, $V_{Th} = 0$. 
**Step 2:** There is no source to zero out in this case. Since it will turn out to be the easier choice, apply a test voltage and measure the resulting current, as shown:

![Circuit Diagram]

To analyze this circuit, first we notice that the voltage drop over each resistor is equal to $V_{\text{Test}}$. This is because the voltage drop between node $a$ and $b$ is $V_{\text{Test}}$, and each resistor is connected to node $a$ on one side and node $b$ on the other.

First we use the I-V relationship of $R_1$.

\[
V_{\text{Test}} = i_1R_1 \quad (6)
\]

\[
i_1 = \frac{V_{\text{Test}}}{R_1} \quad (7)
\]

Then we use the I-V relationship of $R_2$.

\[
V_{\text{Test}} = i_2R_2 \quad (8)
\]

\[
i_2 = \frac{V_{\text{Test}}}{R_2} \quad (9)
\]

Finally, they are combined to calculate the equivalent resistance.

\[
I_{\text{Test}} = i_1 + i_2 = \frac{V_{\text{Test}}}{R_1} + \frac{V_{\text{Test}}}{R_2} \quad (10)
\]

\[
\frac{I_{\text{Test}}}{V_{\text{Test}}} = \frac{1}{R_{\text{Th}}} = \frac{1}{R_1} + \frac{1}{R_2} \quad (11)
\]

Rearranging this expression gives our final resistance:

\[
R_{\text{Th}} = \frac{R_1R_2}{R_1 + R_2} \quad (12)
\]

We call these resistors in **parallel**. Note that in order to be in parallel, the voltage across them has to be the same.

This mathematical relationship comes up often enough that it actually has a name: the “parallel operator”, denoted $\parallel$. When we say $x \parallel y$, it means $\frac{x}{x+y}$. Note that this is a mathematical operator and does not say anything about the actual configuration. In the case of resistors the parallel operator is used for parallel resistors, but for other components (like capacitors) this is not the case.

**From these analyses, we now have a simple rule to tell if elements are in series or parallel.** Series elements will have the exact same current through them due to KCL. Parallel elements will have the exact same voltage across them due to KVL.
4.3 Voltage Divider

Now let’s apply our analysis above to a voltage divider circuit shown below (which is very similar to the touchscreen). To figure out $V_{th}$, we solve for $V_{oc}$ in the following circuit.

Note that the same current flows through the two resistors. In addition, the voltage drop over the two resistors sums to $V_{s}$, so we can write $V_{Rab} = V_{s} - V_{AB,oc}$. Therefore, using Ohm’s Law:

$$I_{Rab} = I_{Rbc}$$
$$\frac{V_{Rab}}{R_{ab}} = \frac{V_{AB,oc}}{R_{bc}}$$
$$\frac{V_{s} - V_{AB,oc}}{R_{ab}} = \frac{V_{AB,oc}}{R_{bc}}$$
$$\frac{V_{s}}{R_{ab}} - \frac{V_{AB,oc}}{R_{ab}} = \frac{V_{AB,oc}}{R_{bc}}$$
$$V_{AB,oc} = \frac{R_{bc}}{R_{ab} + R_{bc}} V_{s}$$

To figure out $R_{th}$, we zero out the independent source and apply a test voltage, measuring the resultant current.

We can see that this is the same as the parallel resistor case we examined above: therefore, $R_{Tth} = \frac{V_{Test}}{I_{Test}} = R_{ab} \parallel R_{bc}$.

This gives us a resulting Thevenin equivalent circuit of:
What if we instead chose the upper two nodes (instead of the lower two nodes) as the two terminals (nodes A and B)? We can follow the same procedure to find an equivalent Thevenin circuit from the standpoint of these new nodes,

After following the same procedure we get the following equivalent circuit:

This is not the same result! In this case, the Thevenin voltages in the two circuits are different. This example shows how different pairs of nodes in the same circuit result in different equivalent circuits. In general, there is no guarantee that circuits will behave in the same way from the standpoint of different pairs of nodes.
5 Summary for Finding Equivalent Resistance

In general, there are three ways of finding the Thevenin/Norton equivalent resistance of a circuit. However, some of them only work in certain situations, so need to be used with caution.

(a) Zero out all independent sources and apply a \( V_{\text{test}} \) or \( I_{\text{test}} \) to calculate the resulting \( I_{\text{test}} \) or \( V_{\text{test}} \) respectively. \( R_{\text{eq}} = \frac{V_{\text{test}}}{I_{\text{test}}} \).

This is the method that we described in detail in the examples above, because **this method works for any circuit**. When in doubt, this method is the most reliable.

(b) Zero out all independent sources and reduce the entire remaining circuit into a single resistor using the series and parallel resistor formulas that were derived in Sections 4.1 and 4.2. **This method does not work if there are dependent sources.** Remember that only independent sources are zeroed out, and there are no resistor formulas for dependent sources. In addition, some resistor configurations cannot be decomposed into combinations of parallel and series resistances.

(c) Calculate \( V_{\text{th}} \) and \( I_{\text{no}} \), \( R_{\text{eq}} = \frac{V_{\text{th}}}{I_{\text{no}}} \). This is an efficient method of finding \( R_{\text{eq}} \) if both the Thevenin and Norton equivalent circuits are being derived. Why does this work? Since the IV relationship is linear, we can calculate the slope (which is the reciprocal of resistance) from any two points. \( V_{\text{th}} \) and \( I_{\text{no}} \) are the points where the IV curve crosses the \( V \) and \( I \) axes, respectively (see the left-hand figure below).

However, this method does not work if \( V_{\text{th}} \) and \( I_{\text{no}} \) do not provide two unique points on the IV curve (see the right-hand figure below). Specifically, **this method only works if there is at least one independent source in the circuit.** When there are no independent sources, \( V_{\text{th}} = I_{\text{no}} = 0 \) which does not provide enough information to calculate \( R_{\text{eq}} \).
